Model Evaluation in Classification

UNIVERSITY
OF WOLLONGONG
AUSTRALIA

Model Evaluation and Selection

- Evaluation metrics: How can we measure accuracy? Other metrics to consider?
- Use a separate **test set** of class-labeled tuples instead of training set when assessing accuracy
- Methods for estimating a classifier's accuracy:
  - Holdout method, random subsampling
  - Cross-validation
  - Bootstrap
- Comparing classifiers:
  - Confidence intervals
  - ROC Curves

Model Evaluation

How do we evaluate our classifiers?

- Positive tuples (P): tuples of the main class of interest (e.g., buys_computers = yes)
- Negative tuples (N): tuples of all other classes
- **True positives** (TP): the positive tuples that were correctly labeled by the classifier.
- **True negatives** (TN): the negative tuples that were correctly labeled by the classifier.
- **False positive/false negative** (FP/FN): the negative/positive tuples that were incorrectly labeled as positive/negative
  - For convivence, we also use P/N/TP/TN/FP/FN to denote the *number* of P/N/TP/TN/FP/FN, respectively.

Classifier Evaluation Metrics: Confusion Matrix

Confusion Matrix:

Actual class\Predicted class	C_1	¬ C_1
C_1	**True Positives (TP)**	**False Negatives (FN)**
¬ C_1	**False Positives (FP)**	**True Negatives (TN)**

Example of Confusion Matrix:

Actual class\Predicted class	buy_computer = yes	buy_computer = no	Total
buy_computer = yes	**6954**	**46**	7000
buy_computer = no	**412**	**2588**	3000
Total	7366	2634	10000

- More generally, given *m* classes, an entry, $\boldsymbol{CM_{i,j}}$ in a **confusion matrix** indicates # of tuples in class *i* that were labeled by the classifier as class *j*
  - May have extra rows/columns to provide totals

Classifier Evaluation Metrics: Accuracy, Error Rate, Sensitivity and Specificity

A\P	C	¬C	
C	**TP**	**FN**	**P**
¬C	**FP**	**TN**	**N**
	P'	**N'**	**All**

- **Classifier Accuracy,** or recognition rate: percentage of test set tuples that are correctly classified

  Accuracy = (TP + TN)/All
- **Error rate:** *1 – accuracy*, or

  Error rate = (FP + FN)/All

- **Class Imbalance Problem**:
  - One class may be *rare*, e.g. fraud, or HIV-positive
  - Significant *majority of the negative class* and minority of the positive class
  - **Sensitivity**: True Positive recognition rate
    - **Sensitivity = TP/P**
  - **Specificity**: True Negative recognition rate
    - **Specificity = TN/N**

Classifier Evaluation Metrics: Precision and Recall, and F-measures

- **Precision**: exactness – what % of tuples that the classifier labeled as positive are actually positive

$$precision = \frac{TP}{TP + FP}$$

- **Recall:** completeness – what % of positive tuples did the classifier label as positive? (equals to sensitivity)
- Perfect score is 1.0

$$recall = \frac{TP}{TP + FN}$$

- In practice, inverse relationship between precision & recall
- ***F* measure (*F_1* or *F*-score)**: harmonic mean of precision and recall,

$$F = \frac{2 \times precision \times recall}{precision + recall}$$

- ***F_β*:** weighted measure of precision & recall (common β value: 2 or 0.5)
  - assigns ß times as much weight to recall as to precision

$$F_\beta = \frac{(1 + \beta^2) \times precision \times recall}{\beta^2 \times precision + recall}$$

Classifier Evaluation Metrics: Example

Actual Class\Predicted class	cancer = yes	cancer = no	Total	Recognition(%)
cancer = yes	**90**	210	**300**	30.00 (*sensitivity*
cancer = no	140	**9560**	**9700**	98.56 (*specificity)*
Total	230	9770	**10000**	96.50 (*accuracy*)

- *Precision* = 90/230 = 39.13%
- *Recall* = 90/300 = 30.00% = Sensitivity

Evaluating Classifier Accuracy: Holdout & Cross-Validation Methods

- **Holdout method**
  - Given data is randomly partitioned into two independent sets
    - Training set (e.g., 2/3) for model construction
    - Test set (e.g., 1/3) for accuracy estimation
  - Random sampling: a variation of holdout
    - Repeat holdout k times, accuracy = avg. of the accuracies obtained
- **Cross-validation** (k-fold, where $k = 10$ is most popular)
  - Randomly partition the data into k *mutually exclusive* subsets, each approximately equal size
  - At i-th iteration, use D_i as test set and others as training set
  - Leave-one-out: k folds where k = # of tuples, for small sized data
  - ***Stratified cross-validation***: folds are stratified so that class dist. in each fold is approx. the same as that in the initial data

Evaluating Classifier Accuracy: Bootstrap

- **Bootstrap Sampling**
  - Works well with small data sets
  - Samples the given training tuples uniformly *with replacement*
    - i.e., each time a tuple is selected, it is equally likely to be selected again and re-added to the training set
- Several bootstrap methods, and a common one is **.632 boostrap**
  - A data set with *d* tuples is sampled *d* times, with replacement, resulting in a training set of *d* samples. The data tuples that did not make it into the training set end up forming the test set. About 63.2% of the original data end up in the bootstrap, and the remaining 36.8% form the test set (since $(1 - 1/d)^d \approx e^{-1} = 0.368$)
  - Repeat the sampling procedure *k* times, overall accuracy of the model:

$$Acc(M) = \frac{1}{k}\sum_{i=1}^{k}(0.632 \times Acc(M_i)_{test\_set} + 0.368 \times Acc(M_i)_{train\_set})$$

Estimating Confidence Intervals: Classifier Models M_1 vs. M_2

- Suppose we have 2 classifiers, M_1 and M_2, which one is better?
- Use 10-fold cross-validation to obtain $\overline{err}(M_1)$ and $\overline{err}(M_2)$
- These mean error rates are just *estimates* of error on the true population of *future* data cases
- What if the difference between the 2 error rates is just attributed to *chance*?
  - Use a **test of statistical significance**
  - Obtain **confidence limits** for our error estimates

Estimating Confidence Intervals: Null Hypothesis

- Perform 10-fold cross-validation
- Assume samples follow a **t distribution** with *k–1* **degrees of freedom** (here, *k=10*)
- Use **t-test** (or **Student's t-test**)
- **Null Hypothesis**: M_1 & M_2 are the same
- If we can **reject** null hypothesis, then
  - we conclude that the difference between M_1 & M_2 is **statistically significant**
  - Chose model with lower error rate

Estimating Confidence Intervals: t-test

- **Pairwise Comparison**
  - For i^{th} round of 10-fold cross-validation, the same cross partitioning is used to obtain $err(M_1)_i$ and $err(M_2)_i$
  - Average over 10 rounds to get $\overline{err}(M_1)$ and $\overline{err}(M_2)$
  - **t-test** computes **t-statistic** with *k-1* **degrees of freedom:**

$$t = \frac{\overline{err}(M_1) - \overline{err}(M_2)}{\sqrt{var(M_1 - M_2)/k}}$$

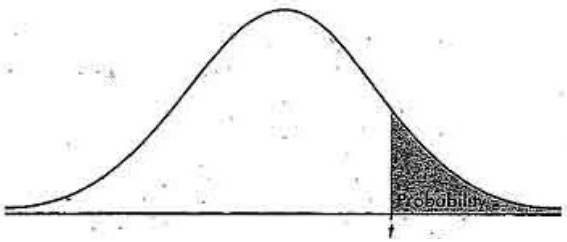
where

$$var(M_1 - M_2) = \frac{1}{k}\sum_{i=1}^{k}\left[err(M_1)_i - err(M_2)_i - (\overline{err}(M_1) - \overline{err}(M_2))\right]^2$$

Estimating Confidence Intervals: Statistical Significance

- Are M_1 & M_2 **significantly different**?
  - Compute *t* and select *significance level* (e.g. *sig = 5%)*
  - Consult the **t-distribution** with k-1 (here k=10) degree of freedom
  - Look for the value *z* in the **t-distribution** corresponding to confidence limit sig/2 (here 0.025)
  - **If** $t > z$ **or** $t < -z$, then *t* lies in rejection region:
    - **Reject null hypothesis** that mean error rates of M_1 & M_2 are same
    - Conclude: statistically significant difference between M_1 & M_2
  - **Otherwise**, conclude that any difference is **by chance**

Estimating Confidence Intervals: Table for t-distribution



- Symmetric
- **Significance level**, e.g., *sig = 0.05* or *5%* means M_1 & M_2 are *significantly different* for 95% of population
- **Confidence limit**, *z = sig/2*

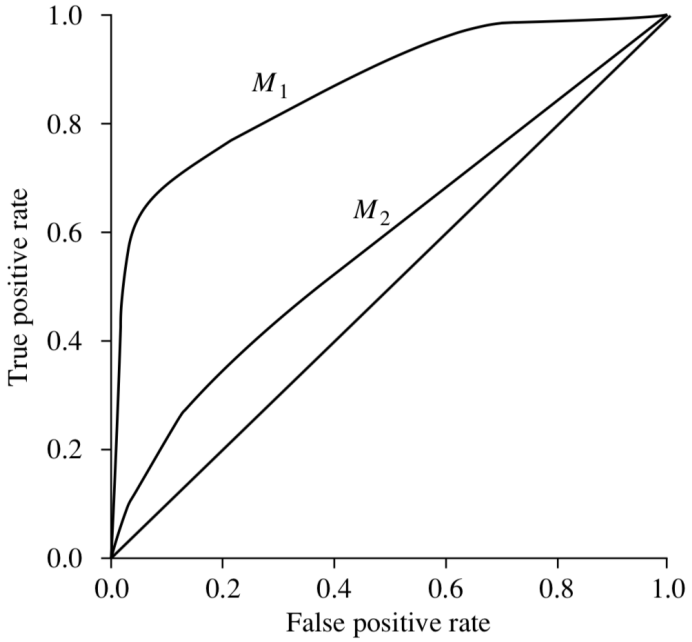
Model Selection: ROC Curves

- **ROC** (Receiver Operating Characteristics) curves: for visual comparison of classification models
- Originated from signal detection theory
- Shows the trade-off between **true positive rate** (TP/P =sensitivity) and **false positive rate** (FP/N=1-specificity)
- The **area under the ROC curve** is a measure of **performance** of the model
- Rank the test tuples in decreasing order: the one that is most likely to belong to the positive class appears at the top of the list
- The closer to the diagonal line (i.e., the closer the area is to 0.5), the less accurate is the model



- Vertical axis represents the true positive rate
- Horizontal axis rep. the false positive rate
- The plot also shows a diagonal line
- A model with perfect accuracy will have an area of 1.0

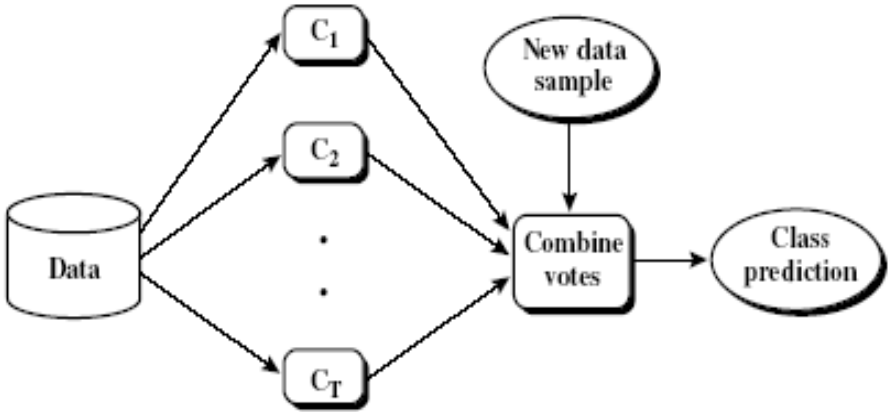
Issues Affecting Model Selection

- **Accuracy**
  - classifier accuracy: predicting class label
- **Speed**
  - time to construct the model (training time)
  - time to use the model (classification/prediction time)
- **Robustness**: handling noise and missing values
- **Scalability**: efficiency in disk-resident databases
- **Interpretability**
  - understanding and insight provided by the model
- Other measures, e.g., goodness of rules, such as decision tree size or compactness of classification rules

Model Enhancement Methods

UNIVERSITY
OF WOLLONGONG
AUSTRALIA

Ensemble Methods:

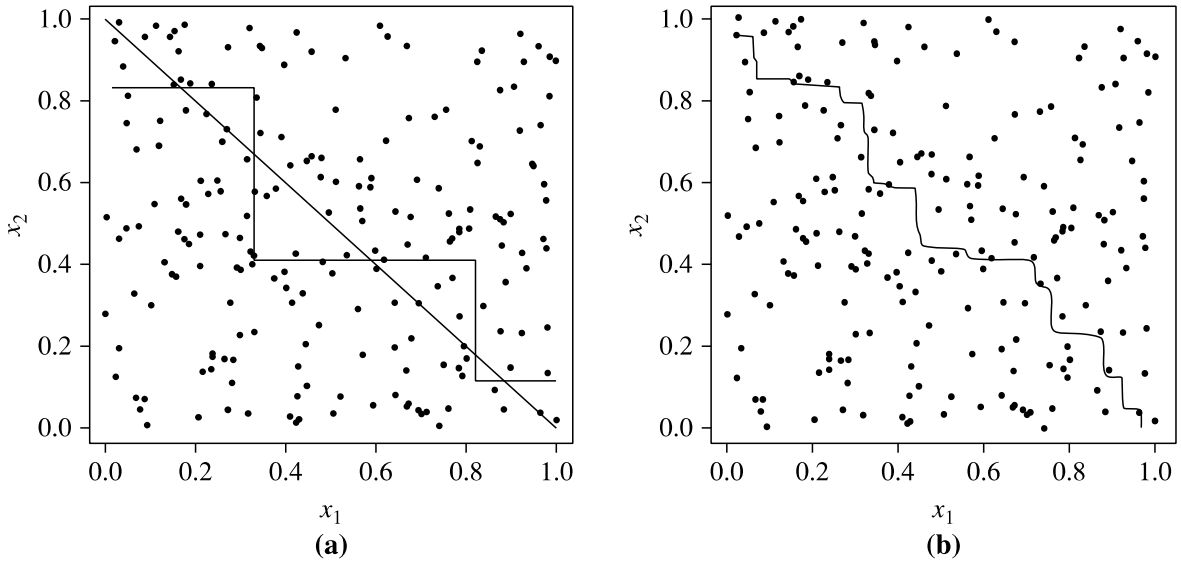


- Ensemble methods
  - Use a combination of models
  - Combine a series of k learned models, M_1, M_2, …, M_k, with the aim of creating a combined model M*
- Popular ensemble methods
  - Bagging: averaging the prediction over a collection of classifiers
  - Boosting: weighted vote with a collection of classifiers
  - Ensemble: combining a set of heterogeneous classifiers

Ensemble Methods:

- Advantages:
  - Increase accuracy: Miss classification occurs only when more than half of base classifiers predict incorrectly (even better if the base classifiers are less correlated.
  - Can deal with data in sheer volume (too many records or attributes)
  - Can run in parallel

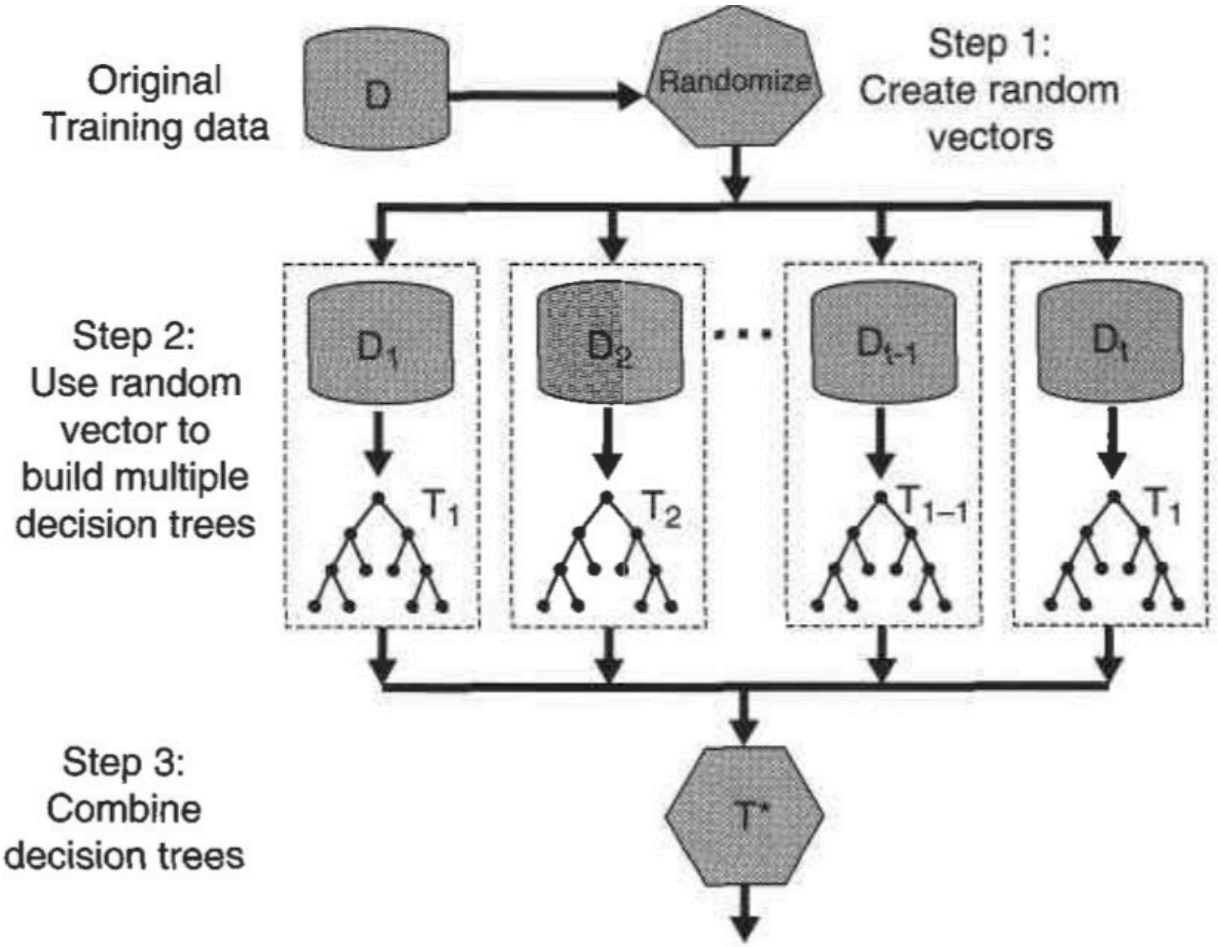
Decision boundary by (a) a single decision tree and (b) a random forest



Random Forest

- Random Forest is a class of ensemble methods specifically designed for decision tree classifiers.
  - It combines the predictions made by multiple decision trees.
  - Each tree is generated randomly based on the training tuples.
  - The final prediction output is produced by a voting function.
- A properly built random forest tends to be more accurate and less biased than individual decision tree classifiers.
  - The accuracy of RF depends on the *strength* of individual classifiers (trees) and a measure of *dependence* between them.
- But the computational cost grows as the number of trees in the forest increases.

Random Forest



Random Forest

- There are 3 common ways to associate randomization with decision trees.
- Bagging: Given a set D of d tuples, bagging works as follows. For iteration i ($i = 1, 2, \ldots, k$), a training set D_i of d tuples is sampled *with replacement* from the original set D.
- Note that some of the original tuples of D may not be included in D_i, whereas others may occur more than once.
- A decision tree M_i is learned for each training set, D_i. To classify an unknown tuple $\boldsymbol{X}$, each classifier M_i returns its class prediction, which counts as one vote.
- The bagged classifier, say, M_* counts the votes and assigns the class with the most votes to $\boldsymbol{X}$.
- Random Forests can handle datasets that don't fit in memory

Random Forest

- Forest-RI (*random input selection*)
  - When building the tree, randomly select F attributes that are used to determine the split at each node, where F is much smaller than the number of available attributes.
  - The CART methodology is used to grow the trees to maximum size
  - If F is sufficiently small, then the trees tend to become less correlated
  - On the other hand, the strength of the tree classifier tends to improve with a larger F
  - As a trade-off, usually let $F = \log_2 m + 1$, where m is the number of input features
  - Since only a subset of the features is selected at each node, this approach helps to significantly reduce the runtime of the algorithm.

Random Forest

- Forest-RC (*random linear combinations*)
  - creates new attributes (or features) that are a linear combination of the existing attributes.
  - That is, an attribute is generated by specifying L, the number of original attributes to be combined.
  - At a given node, L attributes are randomly selected and added together with coefficients that are uniform random numbers on $[-1,1]$.
  - F linear combinations are generated, and a search is made over these for the best split.
  - This form of random forest is useful when there are only a few attributes available, so as to reduce the correlation between individual classifiers.
